1 Problem Formulation

1.1 The Isolated Battery

Let $s \in [0, 1]$ denote the *state of charge* (SOC) of the battery, $h \in [0, 1]$ the *state of health* (SOH), $Q \in \mathbb{R}^+$ the charge, $Q_{00} \in \mathbb{R}^+$ the maximum possible charge at the time of production (in Coulombs), $V \in \mathbb{R}$ the voltage across the battery (in Volts) with $I \in \mathbb{R}$ the corresponding current (in Amperes) where $I > 0$ corresponds to discharging the battery. Then, per common definition, $s := \frac{Q}{Q_0}$ is the amount of charge currently present in the battery as compared to $Q_0 \in \mathbb{R}^+$ the current maximum capacity, which itself is dependent on the state of health, as given by $Q_0 := hQ_{00}$. Further let $T \in [-273.15, \infty)$ denote the temperature of the battery (in degrees Celsius) and let $t \in \mathbb{R}$ represent time (in seconds).

From the definition of current $I := \frac{dQ}{dt}$, we further have that for a single cycle,

$$s = 1 - \frac{1}{Q_0} \int_0^t I(\tau) d\tau,$$

under the assumption that Q_0 , and therefore h , stays constant during that cycle.

Figure 1: The Thevenin equivalent circuit model (ECM) with parameters $R_0 \in \mathbb{R}^+$, $R_1 \in \mathbb{R}^+$ and $C_1 \in \mathbb{R}^+$ and $V_{OC} \in \mathbb{R}^+$ the *open circuit voltage* which behaves according to a function $V_{OC}(s, h, T)$ dependent on s , h and T .

Kirchhoff's law further tells us that the currents $I_{R1} \in \mathbb{R}$ and $I_{C1} \in \mathbb{R}$ add up to the total current $I = I_{R1} + I_{C1}$, and that the voltages $V_0 \in \mathbb{R}$, $V_1 \in \mathbb{R}$ and V_{OC} sum up to $V = V_0 + V_1 + V_{OC}$. The capacitor behaves according to $I_{C1} = C_1 \frac{dV_1}{dt}$, while the resistors follow Ohm's law $V_0 = R_0 I$ and $V_1 = R_1 I_{R1}$.

1.2 Battery in an Electric Vehicle (EV)

On a graph (V_G, E) with edges $E = \{AB, AC, \dots\} \subseteq V_G \times V_G$ and vertices $V_G = \{A, B, \dots\}$, let $d_{AB} \in \mathbb{R}^+$ denote the distance between two vertices $A \in V_G$ and $B \in V_G$ (in meters), $x = x_{AB} \in [0, d_{AB}]$ the progress (current location) on the route from vertex A to B (in meters), $v := \frac{dx}{dt}$ denote the current velocity with $v_{\max, AB} \in \mathbb{R}^+$ the maximum allowed velocity on AB (in meters per second). Then let $T_{\text{env}}(x) \in [-273.15, \infty)$ denote the temperature of the environment (in degrees Celsius) at location x .

Let $P \in \mathbb{R}$, $P := I \cdot V$ denote the (electrical) power the car draws from the battery (in Watts) so $P > 0$ corresponds to discharging the battery. This power is to be realised into a mechanical component $P_{\text{motor}} \in \mathbb{R}^+$ driving the car forwards, heating for the battery $P_{\text{heat}} \in \mathbb{R}^+$, $P_{\text{heat}} = c(T - T_{\text{env}})$, with $c \in \mathbb{R}^+$ the heat conduction constant describing the relation between the heater and battery, and power dissipation $P_{\text{diss}} \in \mathbb{R}^+$. While driving, $P = P_{\text{motor}} + P_{\text{heat}} + P_{\text{diss}}$. The acceleration of the car $a \in \mathbb{R}$ (in meters per second squared), where $a := \frac{dv}{dt} = \frac{d^2x}{dt^2}$ is decomposed into $a_m \in \mathbb{R}$, which directly impacts $P_{\text{motor}}(a_m)$, and the deceleration due to friction (air, etc.) $a_f(v) \in \mathbb{R}^-$, so that in total $a = a_m + a_f$.

On the graph (V_G, E) there exists a set of EV charging stations $V_{\text{charge}} \subseteq V_G$ where $P_{C, \text{charge}}$ denotes the possible charging power (in Watts) at the charging station vertex $C \in V_{\text{charge}}$ with $K_C \in \mathbb{R}^+$ the occurring costs per energy unit (in Euros per Watt second) and $t_C \in \mathbb{R}^+$ the charging time per charging station B (in seconds).

1.3 A Variational Optimisation Problem

Given source and destination vertices $A, Z \in V_G$ on the graph (V_G, E) , which connected set of edges $E_R \subseteq E$ connecting A to Z , battery heating strategy $P_{\text{heat}}(x, v, t, s, h, T_{\text{env}}, \dots)$, $P_{\text{heat}} \in \mathcal{C}(\mathbb{P})$, set of visited charging stations $V_C \subseteq V_{\text{charge}}$ and charging times $\{t_C\}_{C \in V_C}$

visited on the route E_R , and driving behaviour $a_m(x, v, t, s, h, T_{\text{env}}, \dots)$, $a_m \in \mathcal{C}^1(\mathbb{P})$ with \mathbb{P} the parameter space ¹ minimises

1. the total travel time $t_{\text{total}} := \int_{V_R} \frac{1}{v} dx + \sum_{C \in V_C} t_C$,
2. the total cost of travel $K := \sum_{C \in V_C} P_{C, \text{charge}} t_C K_C$,
3. $-N$ where N is the highest possible number of repetitions (commutes from A to Z) with the same battery (requiring $h > 0$).

Formulated differently, we aim to minimise the functional $F \in \mathcal{C}(\mathbb{P})^*$, $F : \mathcal{C}(\mathbb{P}) \mapsto \mathbb{R}$ where either $F[\chi] = t_{\text{total}}$ or $F[\chi] = K$.

Charging station + street data could be obtained from [OpenStreetMap](#) by calling `osmfilter england-latest.o5m keep="amenity=charging_station"` ².

1.4 Aging

2 Numerical Simulation of the Equivalent Circuit Model

2.1 Finding Parameters

2.2 Forward Euler Simulation

3 Metropolis-Hastings and A-Star

3.1 Definition: Undirected Graph

A graph $G = (V, E)$ with vertices V and edges $E \subseteq V \times V$ is undirected if and only if $(v_i, v_j) \in E \Rightarrow (v_j, v_i) \in E \quad \forall v_i, v_j \in V$.

4 Conclusion
